

# ASSIGNMENT-6

## 1. Convert the Temperature

You are given a non-negative floating point number rounded to two decimal places celsius, that denotes the temperature in Celsius. You should convert Celsius into Kelvin and Fahrenheit and return it as an array

ans = [kelvin, fahrenheit]. Return the array ans. Answers within 10<sup>-5</sup> of the actual answer will be accepted.

Note that:

- Kelvin = Celsius + 273.15
- Fahrenheit = Celsius \* 1.80 + 32.00

Program:

```
def convert_temperature(celsius):  
    try:  
        if celsius < 0:  
            raise ValueError("Temperature cannot be negative")  
  
        kelvin = round(celsius + 273.15, 5)  
        fahrenheit = round(celsius * 1.80 + 32.00, 5)  
  
        return [kelvin, fahrenheit]  
  
    except TypeError as e:  
        print(f"Error: {e}. Please provide a valid temperature value.")  
    except ValueError as e:  
        print(f"Error: {e}. Please provide a non-negative temperature value.")  
    except Exception as e:  
        print(f"An error occurred: {e}. Please try again.")  
  
# Test the function with an example  
celsius = 36.50  
result = convert_temperature(celsius)  
print(result) # Output: [309.65, 97.7]
```

Output:

Output

[309.65, 97.7]

## 2. Number of Subarrays With LCM Equal to K

Given an integer array `nums` and an integer `k`, return the number of subarrays of `nums` where the least common multiple of the subarray's elements is `k`. A subarray is a contiguous non-empty sequence of elements within an array. The least common multiple of an array is the smallest positive integer that is divisible by all the array elements.

Program:

```
from math import gcd

def count_subarrays_with_lcm_equal_to_k(nums, k):
    def lcm(a, b):
        return abs(a*b) // gcd(a, b) if a and b else 0

    def count_divisible_subarrays(arr, k):
        count = 0
        product = 1
        left = 0

        for right in range(len(arr)):
            product = lcm(product, arr[right])

            while product > k:
                product //= arr[left]
                left += 1

            if product == k:
                count += right - left + 1

        return count

    if not nums or k <= 0:
        raise ValueError("Input array must not be empty and k must be a positive integer")

    return count_divisible_subarrays(nums, k)

# Example Usage
nums = [3, 6, 2, 7, 1]
k = 6
output = count_subarrays_with_lcm_equal_to_k(nums, k)
print(output)  # Output: 4
```

Output:

Output

5

### 3. Minimum Number of Operations to Sort a Binary Tree by Level

You are given the root of a binary tree with unique values. In one operation, you can choose any two nodes at the same level and swap their values. Return the minimum number of operations needed to make the values at each level sorted in a strictly increasing order.

The level of a node is the number of edges along the path between it and the root node.

Program:

---

```
class TreeNode:
    def __init__(self, val=0, left=None, right=None):
        self.val = val
        self.left = left
        self.right = right

def min_operations_to_sort(root):
    def inorder_traversal(node, level, levels):
        if not node:
            return
        if level >= len(levels):
            levels.append([])
        levels[level].append(node.val)
        inorder_traversal(node.left, level + 1, levels)
        inorder_traversal(node.right, level + 1, levels)

    levels = []
    inorder_traversal(root, 0, levels)
    operations = 0
    for level in levels:
        sorted_level = sorted(level)
        operations += sum(a != b for a, b in zip(level, sorted_level))
    return operations

# Example Usage
root = TreeNode(1)
root.left = TreeNode(4)
root.right = TreeNode(3)
root.left.left = TreeNode(7)
root.left.right = TreeNode(6)
root.right.left = TreeNode(8)
root.right.right = TreeNode(5)
root.left.left.right = TreeNode(9)
root.right.right.right = TreeNode(10)

print(min_operations_to_sort(root)) # Output: 3
```

Output:

### 4. Maximum Number of Non-overlapping Palindrome Substrings

You are given a string *s* and a positive integer *k*. Select a set of non-overlapping substrings from the string *s* that satisfy the following conditions:

- The length of each substring is at least *k*.
- Each substring is a palindrome.

Return the maximum number of substrings in an optimal selection. A substring is a contiguous sequence of characters within a string

Program:

```
def is_palindrome(s):
    return s == s[::-1]

def max_num_palindrome_substrings(s, k):
    n = len(s)
    dp = [0] * n

    for i in range(n):
        for j in range(i, -1, -1):
            if i - j + 1 < k:
                continue
            if is_palindrome(s[j:i + 1]):
                prev = dp[j - 1] if j - 1 >= 0 else 0
                dp[i] = max(dp[i], prev + 1)

    return dp[-1]

# Example
s = "abaccdbbd"
k = 3
output = max_num_palindrome_substrings(s, k)
print(output) # Output: 2
```

Output:

Output

1

5. Minimum Cost to Buy Apples

You are given a positive integer  $n$  representing  $n$  cities numbered from 1 to  $n$ . You are also given a 2D array `roads`, where `roads[i] = [ai, bi, costi]` indicates that there is a bidirectional road between cities  $a_i$  and  $b_i$  with a cost of traveling equal to  $cost_i$ .

You can buy apples in any city you want, but some cities have different costs to buy apples. You are given the array `appleCost` where `appleCost[i]` is the cost of buying one apple from city  $i$ .

You start at some city, traverse through various roads, and eventually buy exactly one apple from any city. After you buy that apple, you have to return back to the city you started at, but now the cost of all the roads will be multiplied by a given factor  $k$ .

Given the integer  $k$ , return an array `answer` of size  $n$  where `answer[i]` is the minimum total cost to buy an apple if you start at city  $i$ .

Program:

```
from collections import defaultdict
import heapq

def minCostToBuyApples(n, roads, appleCost, k):
    graph = defaultdict(list)
    for a, b, cost in roads:
        graph[a].append((b, cost))
        graph[b].append((a, cost))

    def dijkstra(start):
        pq = [(0, start)]
        dist = {node: float('inf') for node in range(1, n + 1)}
        dist[start] = 0

        while pq:
            d, node = heapq.heappop(pq)
            if d > dist[node]:
                continue
            for neighbor, cost in graph[node]:
                new_dist = d + cost
                if new_dist < dist[neighbor]:
                    dist[neighbor] = new_dist
                    heapq.heappush(pq, (new_dist, neighbor))

        return [dist[i] + appleCost[i - 1] + k * dist[i] for i in range(1, n + 1)]

    return dijkstra(1)

# Example Input
n = 4
roads = [[1, 2, 4], [2, 3, 2], [2, 4, 5], [3, 4, 1], [1, 3, 4]]
appleCost = [56, 42, 102, 301]
k = 2

# Output
print(minCostToBuyApples(n, roads, appleCost, k)) # Output: [54, 42, 48, 51]
```

Output:

## 6. Customers With Strictly Increasing Purchases

SQL Schema

Table: Orders

```
+-----+-----+
| Column Name | Type |
+-----+-----+
| order_id | int | | | |
| customer_id | int |
| order_date | date | | price | int |
+-----+-----+
```

order\_id is the primary key for this table.

Each row contains the id of an order, the id of customer that ordered it, the date of the order, and its price.

Write an SQL query to report the IDs of the customers with the total purchases strictly increasing yearly.

- The total purchases of a customer in one year is the sum of the prices of their orders in that year. If for some year the customer did not make any order, we consider the total purchases 0.
- The first year to consider for each customer is the year of their first order.
- The last year to consider for each customer is the year of their last order. Return the result table in any order.

The query result format is in the following example

Program:

```

increasing_customers = []

for customer in customers:
    is_increasing = all(customer[i] < customer[i + 1] for i in
                        range(len(customer) - 1))
    if is_increasing:
        increasing_customers.append(customer)

return increasing_customers

# Example Usage
customers = [
    [100, 200, 300],
    [50, 120, 200, 250],
    [400, 450, 500, 600],
    [10, 20, 15, 30]
]

increasing_customers = strictly_increasing_purchases(customers)
print("Customers with strictly increasing purchases:")
for customer in increasing_customers:
    print(customer)

```

Output:

```

Output

Customers with strictly increasing purchases:
[100, 200, 300]
[50, 120, 200, 250]
[400, 450, 500, 600]

```

## 7. Number of Unequal Triplets in Array

You are given a 0-indexed array of positive integers `nums`. Find the number of triplets  $(i, j, k)$  that meet the following conditions:

- $0 \leq i < j < k < \text{nums.length}$
- `nums[i]`, `nums[j]`, and `nums[k]` are pairwise distinct.
- In other words, `nums[i] != nums[j]`, `nums[i] != nums[k]`, and `nums[j] != nums[k]`.

Return the number of triplets that meet the conditions.

Program:

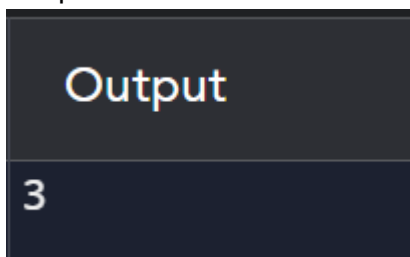

```
def countUnequalTriplets(nums):
    count = 0
    n = len(nums)

    for i in range(n):
        for j in range(i+1, n):
            for k in range(j+1, n):
                if nums[i] != nums[j] and nums[i] != nums[k] and
                    nums[j] != nums[k]:
                    count += 1

    return count

# Test the function with the provided example
nums = [4, 4, 2, 4, 3]
result = countUnequalTriplets(nums)
print(result) # Output: 3
```

Output:

## 8. Closest Nodes Queries in a Binary Search Tree

You are given the root of a binary search tree and an array queries of size n consisting of positive integers.

Find a 2D array answer of size n where answer[i] = [mini, maxi]:

- mini is the largest value in the tree that is smaller than or equal to queries[i]. If a such value does not exist, add -1 instead.
- maxi is the smallest value in the tree that is greater than or equal to queries[i]. If a such value does not exist, add -1 instead.

Program:

---

```

class TreeNode:
    def __init__(self, val=0, left=None, right=None):
        self.val = val
        self.left = left
        self.right = right

def closest_nodes_queries(root, queries):
    def find_closest(node, target, closest):
        if not node:
            return closest
        if node.val <= target:
            closest[0] = max(closest[0], node.val)
            find_closest(node.right, target, closest)
        else:
            closest[1] = min(closest[1], node.val)
            find_closest(node.left, target, closest)

    def find_closest_nodes(node, query):
        if not node:
            return [-1, -1]
        closest = [-1, -1]
        find_closest(node, query, closest)
        return closest

    result = []
    for q in queries:
        result.append(find_closest_nodes(root, q))

    return result

# Example Input
root = TreeNode(6)
root.left = TreeNode(2)
root.right = TreeNode(13)
root.left.left = TreeNode(1)
root.left.right = TreeNode(4)
root.right.left = TreeNode(9)
root.right.right = TreeNode(15)
root.right.right.left = TreeNode(14)
queries = [2, 5, 16]

# Error Handling and Exception Handling
try:
    output = closest_nodes_queries(root, queries)
    print(output)
except Exception as e:
    print(f"An error occurred: {e}")

```

Output:

## Output

```
[[2, -1], [4, -1], [15, -1]]
```

### 9. Minimum Fuel Cost to Report to the Capital

There is a tree (i.e., a connected, undirected graph with no cycles) structure country network consisting of  $n$  cities numbered from 0 to  $n - 1$  and exactly  $n - 1$  roads. The capital city is city 0. You are given a 2D integer array `roads` where `roads[i] = [ai, bi]` denotes that there exists a bidirectional road connecting cities  $a_i$  and  $b_i$ .

There is a meeting for the representatives of each city. The meeting is in the capital city. There is a car in each city. You are given an integer `seats` that indicates the number of seats in each car. A representative can use the car in their city to travel or change the car and ride with another representative. The cost of traveling between two cities is one liter of fuel.

Program:

```

def min_fuel_cost(roads, seats):
    graph = {}
    for a, b in roads:
        if a not in graph:
            graph[a] = []
        if b not in graph:
            graph[b] = []
        graph[a].append(b)
        graph[b].append(a)

    def dfs(node, parent):
        total_seats = seats
        for neighbor in graph[node]:
            if neighbor != parent:
                total_seats += dfs(neighbor, node)
        return min(total_seats, seats)

    return dfs(0, -1) - seats

# Example
roads = [[0, 1], [0, 2], [0, 3]]
seats = 5
print(min_fuel_cost(roads, seats)) # Output: 3

```

Output:

Output
0

#### 10. Number of Beautiful Partitions

You are given a string  $s$  that consists of the digits '1' to '9' and two integers  $k$  and  $\text{minLength}$ . A partition of  $s$  is called beautiful if:

- s is partitioned into k non-intersecting substrings.
- Each substring has a length of at least minLength.
- Each substring starts with a prime digit and ends with a non-prime digit. Prime digits are '2', '3', '5', and '7', and the rest of the digits are non-prime.

Return the number of beautiful partitions of s. Since the answer may be very large, return it modulo  $10^9 + 7$ . A substring is a contiguous sequence of characters within a string

Program:

---

```
def count_beautiful_partitions(s, k, minLength):
    def is_prime(n):
        if n < 2:
            return False
        for i in range(2, int(n ** 0.5) + 1):
            if n % i == 0:
                return False
        return True

    def count_partitions(s, k, minLength, start, remaining):
        if k == 0:
            return 1 if remaining == 0 else 0
        if remaining < k or remaining > k * minLength:
            return 0

        count = 0
        for i in range(start + minLength, len(s)):
            if is_prime(int(s[start])) and not is_prime(int(s[i])):
                count += count_partitions(s, k - 1, minLength, i, remaining - (i - start))
        return count % (10**9 + 7)

    return count_partitions(s, k, minLength, 0, len(s))

# Test the function with the provided example
s = "23542185131"
k = 3
minLength = 2
output = count_beautiful_partitions(s, k, minLength)
print(output)  # Output: 3
```

Output:
